Abstract

Purpose: The aim of this study was to compare the effects of cold-water immersion and whole-body cryotherapy on recovery kinetics following exercise induced muscle damage.

Methods: Ten physically active men performed single-leg hamstring eccentric exercise comprising 5 sets of 15 repetitions. Immediately post-exercise, subjects were exposed in a randomized cross-over design to cold-water immersion (10 minutes at 10°C) or whole-body cryotherapy (3 minutes at -110°C) recovery. Creatine kinase concentrations, knee flexor eccentric ($60^{\circ} \cdot s^{-1}$) and posterior lower limb isometric (60°) strength, single-leg and two leg countermovement jump, muscle soreness and perception of recovery were measured. The tests were performed before, immediately, 24h, 48h and 72h after exercise. **Results:** Results showed a very likely moderate effect in favour of cold-water immersion for single-leg [Effect Size (ES) = 0.63; 90% Confidence Interval (CI) = -0.13 to 1.38] and two-leg countermovement jump (ES = 0.68; 90% CI = -0.08 to 1.43) 72h after exercise. Soreness was moderately lower 48h after exercise following cold-water immersion (ES = -0.68; 90% CI = -1.44 to 0.07). Perception of recovery was moderately enhanced 24h after exercise for cold-water immersion (ES = -0.62; 90% CI = -1.38 to 0.13). Trivial and small effects of condition were found for the other outcomes. **Conclusion:** Cold-water immersion was more effective in accelerating recovery kinetics than whole-body cryotherapy for countermovement jump performance at 72h post-exercise. Cold-water immersion also demonstrated lower soreness and higher perceived recovery levels across 24-48h post-exercise.

Key words: eccentric, muscle damage, cold-air, fatigue.

Introduction

Cooling the body to accelerate the recovery of performance is now widely used by coaches and athletes.¹ One of the theoretical bases of cooling the body to accelerate recovery is a decrease in inflammation due to exposure to the cold environment.^{2, 3} Inflammation occurs immediately following exercise induced muscle damage and is prolonged over time.⁴ Although this inflammatory response is required to heal muscle damage,⁴ an attenuation of this inflammation may have beneficial effects on recovery of muscle performance.²

The principle of cold-water immersion (CWI) is to immerse a part, or all of the body (except the head) in a cold-water bath in which the temperature is below 15°C for a duration of 10 to 12 minutes.⁵ In contrast, whole-body cryotherapy (WBC) consists of body exposure to very-cold air at a temperature between -110°C to -195°C in a specifically designed room, for a total duration of 3 to 4 minutes.³

Studies have shown the ability of CWI to improve strength and power recovery kinetics following exercise induced muscle damage in comparison with a passive recovery.⁶

Similarly, Hausswirth et al.⁷ and Ferreira-Junior et al.⁸ found a beneficial effect of WBC on recovery kinetics in comparison with far-infrared and passive recovery conditions, respectively. Two systems are frequently used for whole-body cryotherapy: cold air⁷ or liquid nitrogen.⁸ In the cold-air system, the chamber is closed and subjects have to traverse a first room at a temperature of -10°C. They traversed a second room at a temperature of -60°C. and stay 3 minutes in a room at a temperature of -110°C. In the liquid nitrogen system subjects are exposed 3 minutes at a temperature of -110°C. In this system the head is not exposed to cold.

CWI and WBC have a significant effect on reducing some biological markers of muscle damage^{3, 9} and inflammation.³ Additionally, these recovery strategies have also been shown to provide a beneficial effect on subjectively perceived soreness the day after

exercise.^{9,6} However, the efficacy of CWI is not clearly established despite the large volume of research performed in this area.⁹ Roberts et al.¹⁰ found that regular post-exercise CWI may attenuate muscular adaptations to resistance training.

In a meta-analysis, Poppendieck et al.¹¹ compared the effects on recovery of CWI versus WBC. They found a slightly higher average effect size on performance recovery for CWI. However, in this review only two studies regarding WBC effects on recovery kinetics were reported. Differences between CWI or WBC protocols make the comparison between both recovery strategies difficult. Parameters such as magnitude of strength loss following the exercise implemented or the type of exercise task used vary from one study to another.^{8,12} To the best of our knowledge, no study has compared CWI with WBC for effects on muscle performance recovery kinetics, biochemical markers of muscle damage and perceived soreness. Therefore, the aim of this study was to compare the effects of cold-water immersion and whole-body cryotherapy on recovery kinetics following exercise induced muscle damage.

Methods

Experimental design

In a randomized crossover design, subjects performed 5 sets of 15 eccentric knee flexors contractions on one leg to induce muscle damage. Immediately after, subjects performed either a CWI or a WBC recovery session. Each session was separated by two weeks. Subjects performed a battery of tests before the exercise (baseline values), immediately after (0h), and 24h, 48h and 72h after the exercise induced muscle damage.

Subjects

Of the fourteen initial participants, four subjects were excluded: two incurred an injury and two did not respect the inclusive criteria. Ten physically active men (age: 23.4±4

years; height: 178 ± 9 cm; body mass: 73.4 ± 12.0 kg) participated in this study: they had not incurred any hamstring injury during the prior six months. Subjects were asked not to undertake any physical activity at least 48 hours prior to the completion of the first test (baseline). They were instructed not to perform any physical activity, not to consume protein, alcohol or caffeine nor to perform any recovery strategies in the 24 hours before the exercise inducing muscle damage and also during the 3 days following the exercise. The level of hamstring soreness and the level of fatigue had to be lower than 5 (moderately sore/tired) on a 0 to 10 point scale (0 = not sore; 10 = very, very sore) and (0 = not tired; 10 = very, very tired), respectively. Each subject answered a questionnaire before each session to check if these criteria were respected. If the participants did not respect these inclusion criteria they were excluded from the study. All subjects provided written informed consent to participate to this study. This study was made in accordance with the local ethical committee on biomedical research (N°5915052012) and the standards set by the Declaration of Helsinki.

Methodology

Subjects' allocation: Subjects were allocated in a randomized and balanced order to both conditions: CWI and WBC. Dominant and non-dominant legs were assigned to a condition in a randomized and balanced order. The order of recovery session was also randomized and 4 combinations were used: non-dominant leg + CWI, dominant leg + CWI, non-dominant leg + WBC, dominant leg + WBC. Randomization of participants was conducted by using a random-numbers generator (www.randomization.com) to assign subjects to their groups. To avoid cross adaptation consequences of the contralateral leg on force values and recovery kinetics¹³ half of the group started with CWI and the other half with WBC.

Familiarization and tests: Subjects performed two sessions of familiarization consisting of 5 repetitions of the test at a low intensity and two repetitions at a maximal intensity. Two sessions were performed to determine the level of reliability for eccentric force, isometric force and CMJ-1L tests. Reliability statistics were calculated between trial 1 and trial 2 (table 1) at the baseline time point. Trial 1 and trial 2 were separated by 72h. Baseline values were recorded before the experimental protocol. During each session, the investigator verbally encouraged subjects to perform at their best. Encouragements were standardized. Each session was preceded by a standardized warm-up.

Warm-up: The warm-up comprised 2 sets of 10 repetitions of concentric contractions with one-minute recovery between sets on an isokinetic dynamometer (Con-Trex MJ, CMV AG, Dübendorf, Switzerland). The subjects performed knee flexions at $60^{\circ} \cdot s^{-1}$ at a fixed intensity of $60 \text{ N} \cdot \text{m}^{-1}$.

Exercise-induced muscle damage: Subjects performed a hamstring exercise (knee flexion) task using the tested leg on an isokinetic dynamometer (as above). The exercise task comprised 5 sets of 15 eccentric contractions at a speed of $60^{\circ} \cdot s^{-1}$, interspersed by a 3 minute recovery. Each contraction lasted 3 seconds and recovery time between contractions lasted 3 seconds.

Subjects were seated on the dynamometer chair, with the hip joint at 75° . Full extension of the leg was considered as 0° for dynamic tests (range of motion $0-90^{\circ}$). The distal shin pad of the dynamometer was attached 3-4 cm proximal to the lateral malleolus by using a strap. During muscle contractions, to minimize extraneous body movements, straps were applied across the chest, pelvis and mid-thigh. The alignment between the dynamometer rotational axis and the knee joint rotation axis (lateral femoral condyle) was checked at the beginning of each trial. Gravity's effect on torque was recorded on each subject throughout the range of motion, and this was used to correct torque measurements during all tests. The

isokinetic dynamometer was calibrated according to the recommendations of the manufacturer. Thirty minutes after completing exercise the subjects noted the global intensity using the modified rate of perception scale from 0 (rest) to 10 (maximal).¹⁴

Recovery sessions: These took place 5 minutes after the last test was performed, which corresponds to 0h after the exercise task. During CWI, in a standing position, subjects wore swimming trunks and were immersed up to the neck in a cold-water pool at 10°C for 10 minutes.⁵ During WBC subjects were in a cryocabin (Cryo Sana, Mecacel, France) producing cold air from liquid nitrogen at a temperature of -110°C for 3 minutes.⁸ Skin was directly exposed to cold except the head (which was outside the top of the cabin) and the hands and feet while inside the cabin, were protected by gloves, socks and clogs. Exercise and recovery sessions were performed in a room with a temperature of 21°C.

Force tests: Subjects were tested on an isokinetic dynamometer (as above) in knee flexion at different speeds and on different types of muscular contractions: eccentric force (60°.s⁻¹) and isometric force (5 seconds at 60°). Subjects performed two trials interspersed by three-minute recovery for each kind of contraction. Force was tested immediately post-exercise (0h), then at 24h, 48h and 72h post-exercise.

Single-leg (CMJ-1L) and two-legs (CMJ-2L) countermovement jump: Subjects performed the jumps on a force plate (Kistler Instruments, Hampshire, UK). They kept the foot of the tested leg in contact with the platform, with their hands on the hips. Their knee was flexed to a self-selected depth in response to the instruction to jump as high as possible, and to land on the same leg. The platform was calibrated according to the manufacturer recommendations. Single leg countermovement jump was performed before CMJ-2L. Subjects performed two trials interspersed by one-minute recovery for each kind of jump. For CMJ-2L, Nedelec et al.¹⁵ found a high reliability. The typical error was 1.5 cm, the intra-class correlation coefficient 0.92 and the coefficient of variation 2.9%. Test re-test reliability of

CMJ-1L is presented in table 1. The typical error was 0.85 cm (90% CI= 0.5 to 2.5), the intra-class correlation coefficient 0.97 (90% CI= 0.8 to 0.99) and the coefficient of variation 9.4%. Single-leg and two-leg countermovement jumps were assessed immediately post-exercise (0h), then 24h, 48h and 72h post-exercise.

Creatine kinase: Blood samples were taken from 32µl fingertip capillary punctures to assess plasma creatine kinase concentrations [CK]. Blood was placed on a measurement strip and analyses were done using a Reflotron (Roche Diagnostics, Grenzachstrasse, Switzerland). The Reflotron was calibrated according to the manufacturer recommendations. Previous work by Horder et al.¹⁶ showed a between-day coefficient of variation of 4.2% for [CK] measures with the Reflotron. Plasma [CK] was measured before exercise, then 24h, 48h and 72h post-exercise.

Muscle soreness and Perceived recovery: Subjects were asked to rate their level of perceived hamstring muscle soreness using a Likert scale from 0 (not sore) to 10 (very, very sore).¹⁷ Subjects rated their level of perceived recovery using a recovery scale from 0 (very well recovered) to 10 (very poorly recovered). The scale used here was adapted from Laurent et al.,¹⁸ who established this scale, but with an inverse number order (i.e. 0 was “very poorly recovered”). The numbers were changed here to achieve coherence between the recovery and soreness scales (i.e. from positive to negative perception). Muscle soreness was rated pre-exercise, immediately post-exercise (0h: before the recovery session), then 24h, 48h and 72h after exercise. Perceived recovery was rated immediately post-exercise (0h: after the recovery session), then 24h, 48h and 72h after exercise.

Statistical analysis

Data are presented as mean \pm standard deviation (SD). Values for force, CMJ-1L, CMJ-2L and [CK] were normalized to 100%. A small effect size was found for the difference

of the baseline values between CWI and WBC for all outcomes. The effect of time and the effect of condition on the dependent variables – force, CMJ-1L, CMJ-2L, [CK], soreness and perceived recovery– were analysed using the following criteria: ≥ 0 to ≤ 0.2 = trivial; 0.21 to ≤ 0.6 = small; 0.61 to ≤ 1.2 = moderate; 1.21 to ≤ 2 = large; 2.1 to ≤ 4 = very large; ≥ 4 = nearly perfect.¹⁹ To calculate the effect size, the mean difference was defined as CWI value – WBC value for all the outcomes. Confidence interval (CI) was set at 90%. Probability to have a higher effect of a condition compared to the other was assessed qualitatively as follows: $<0.5\%$, most unlikely or almost certainly not; 0.5–5%, very unlikely; 5.1–25%, unlikely or probably not; 25.1–75%, possibly; 75.1–95%, likely or probably; 95.1–99.5%, very likely; $>99.5\%$, most likely or almost certainly. If the probability to have results in favour of both treatments were $>5\%$, the true difference was assessed as unclear.²⁰ The percentage of chance is presented in favour of: cold-water immersion/trivial/whole-body cryotherapy. For reliability of eccentric force, isometric force, and CMJ-1L the coefficient of variation (CV), intraclass correlation coefficient (ICC), 90% confidence intervals (CI) and typical error (TE) were calculated.²¹

Results

Rate of perceived exertion

A trivial effect size (-0.09 ; 90% CI = -0.96 to 0.79) was found for the difference of mean RPE collected after exercise for the CWI condition (6.3 ± 2.4) and the WBC condition (6.5 ± 2.1).

Reliability

Interday test-retest reliability for eccentric force, isometric force and CMJ-1L was calculated. Results are presented in Table 1.

Time effect

Effect sizes and 90% CI of each time point in comparison with baseline values are presented in Table 2 for eccentric force, isometric force, CMJ-2L, CMJ-1L, soreness, perception of recovery and [CK] for each condition. A large to very large effect of time was found for all the outcomes across the 72h except CMJ-1L 72h post exercise and [CK] 48h post-exercise. Figures 1 to 4 display the change over time for the different variables.

Condition effect

Effect sizes and 90% CI of between-condition effect are presented in Figures 1 to 4. Probabilities of chances to have an effect in favour of a condition are also presented in figures 1 to 4 for eccentric force, isometric force, CMJ-2L, CMJ-1L, soreness, perception of recovery and [CK]. An effect of condition was found in favour of CWI for CMJ-1L and CMJ-2L 72h post-exercise (figure 2), muscle soreness 48h post-exercise and perceived recovery 24h post-exercise (figure 3). Creatine kinase concentrations were largely and moderately lowered in the CWI condition in comparison with the WBC condition 24h and 72h after exercise, respectively.

Discussion

The aim of this study was to compare the effects of cold-water immersion and whole-body cryotherapy on recovery kinetics following exercise induced muscle damage. Results showed that, in comparison with WBC, a very likely moderate effect in favour of CWI was evident for accelerating CMJ-1L and CMJ-2L recovery 72h after exercise. In addition, a likely moderate effect in favour of CWI was found for lower muscle soreness 48h after exercise and better perceived recovery 24h after exercise. A very likely large effect and a likely moderate effect in favour of CWI were found for lower [CK] 24h and 72h after

exercise, respectively. For eccentric and isometric force development the effect was unclear across 72h of recovery.

For this experiment to be useful, it was important to establish that the exercise task chosen did induce significant muscle damage. Muscle force loss is considered to be one of the best tools for quantifying muscle damage.²² The results confirm the effectiveness of the chosen exercise task, as large to very large effects of time in both conditions were reported in force decrement (Table 2). Height of CMJ-2L was also affected by the exercise in both recovery conditions, as large to very large effects of time were found. This effect was less pronounced in single leg jumps, as a moderate time effect was detected for CMJ-1L across the 72h post-exercise recovery period in the WBC condition, and moderate to large time effects only up to 48h post-exercise in the CWI condition. Nevertheless, sufficiently high force and jump performance decrements were noted across 72h of recovery, to allow an assessment of the effectiveness of the two recovery procedures.

When comparing the conditions, CWI was found more likely to improve recovery kinetics of CMJ-1L and CMJ-2L at 72h post-exercise. Muscle power recovery assessed from CMJ-1L and CMJ-2L was faster following CWI than WBC. The larger effect of CWI on recovery kinetics could be partly explained by the rate of heat transfer (Q). Water (0.58 W/(m-K)) has a 24.2 times higher heat-transfer coefficient (k) than air (0.024 W/(m-K)): as such, water is more efficient for extracting heat energy from the body than air.²³ In further contrast to cold-air, cold-water exerts a hydrostatic pressure on the body.² Previous work has found that CWI and hot-water immersion are both effective in improving muscle strength recovery in comparison with passive recovery, but CWI is more effective than hot-water immersion.²⁴ Together, these data indicate that the combination of cold and hydrostatic pressure may act together to improve performance recovery kinetics. It can be hypothesized that the faster recovery kinetics with cold-water immersion may be at least partially linked

with the capacity of water to extract heat combined with the hydrostatic pressure. Cold-water immersion is more effective than hot water immersion in accelerating muscle recovery²⁴ indicating that cold may be a factor that accelerates muscle recovery. Water (0.58 W/(m-K)) has a 24.2 times higher heat-transfer coefficient (k) than air (0.024 W/(m-K))²³ and CWI may decrease skin temperature for a longer duration than WBC. As recovery kinetics of muscular force were not different between CWI and WBC, one can suggest that CWI enhanced speed recovery faster than WBC.

Whole-body cryotherapy and cold-water immersion have both demonstrated the ability to decrease muscle soreness across 72h post-exercise.^{6, 25} The results suggest that CWI was more effective in decreasing muscle soreness at 48h post-exercise, and that perceived recovery was higher at 24h after exercise. These findings are consistent with a recent meta-analysis⁶ that reported a lower general fatigue after exercise for subjects using CWI in comparison with passive recovery. With regard to potential mechanisms, Algafly and George²⁶ found that pain threshold and pain tolerance were increased and nerve conduction velocity of the tibial nerve was reduced following direct ice application on the ankle. Applying pressure with compression garments to muscles has also been shown to decrease perceived muscle soreness.²⁷ As cold-water can decrease skin temperature for a longer period than air²⁹ and also exerts a pressure on the body,² it can be hypothesized that this longer temperature decrease combined with the pressure exerted by water may have also increased pain tolerance.

Similar to other studies,⁷ [CK] increased after the muscle damaging exercise. A large effect of time was found 24h and 72h post-exercise and a moderate effect of time was found 48h post-exercise in the CWI condition. Very large and large effects were found 24h, 48h and 72h post-exercise, respectively, in the WBC condition. For the condition effect, a very likely

large effect and a likely moderate effect in favour of CWI, respectively 24h and 72h post-exercise, suggesting a higher effectiveness of CWI in comparison with WBC.

Limitations

This study presents some limitations. Firstly, the sample size was too small for some of the variables studied. A statistical power test was performed, retrospectively, for the following variables: eccentric force (power = 1), isometric force (power = 1), CMJ-1L (power = 0.18), and CMJ-2L (power = 0.35). Secondly, due to the cross-over design and the fact that subjects performed a single-leg exercise, it was not possible to implement a true control condition. Having a control condition would have allowed an analysis of the efficiency of each recovery procedure in comparison with a passive recovery. Thirdly, muscle and skin temperatures were not measured in this study, and may have provided useful information on the heat exchange afforded by each recovery procedure. According to the study of Costello et al.,²⁸ who compared vastus lateralis and thigh skin temperature decrease between CWI (4 minutes at 8°C) and WBC (20 seconds at -60°C and 3 minutes and 40 seconds at -110°C), a 2°C-drop in muscle temperature (3 cm below the subcutaneous fat layer) can be expected 60 minutes after exposure in both conditions. In the CWI condition a 9°C-drop in skin temperature can be expected immediately after exposure and a 5°C-drop can be expected 60 minutes after exposure. In the WBC condition a 12°C-drop can be expected immediately after exposure and a 4°C-drop can be expected 60 minutes after exposure. The amplitude of confidence intervals obtained for force were very large, spanning all levels of magnitude and potentially leading to unclear results.²⁰

Practical applications

This study shows that, in this hamstring damaging protocol, using CWI was more beneficial than WBC to improve muscle power recovery 72h after the exercise. Implementing CWI is a potentially useful strategy to accelerate recovery after an exercise inducing muscle-damage.

Conclusion

To our knowledge this study is the first to directly compare CWI and WBC effects on performance recovery following exercise induced muscle damage. The results showed that CWI may be more efficient in accelerating recovery kinetics than WBC for single-leg and two-leg countermovement jumps at 72h post-exercise. Although no differences in strength recovery were found between the two procedures, CWI did lower ratings of muscle soreness and increase perceived recovery across 24-48h post-exercise. In perspective, it would be interested to study the effects of both strategies for repeated treatments at 24h and 48h post-exercise on recovery kinetics and the repeated bout effect.

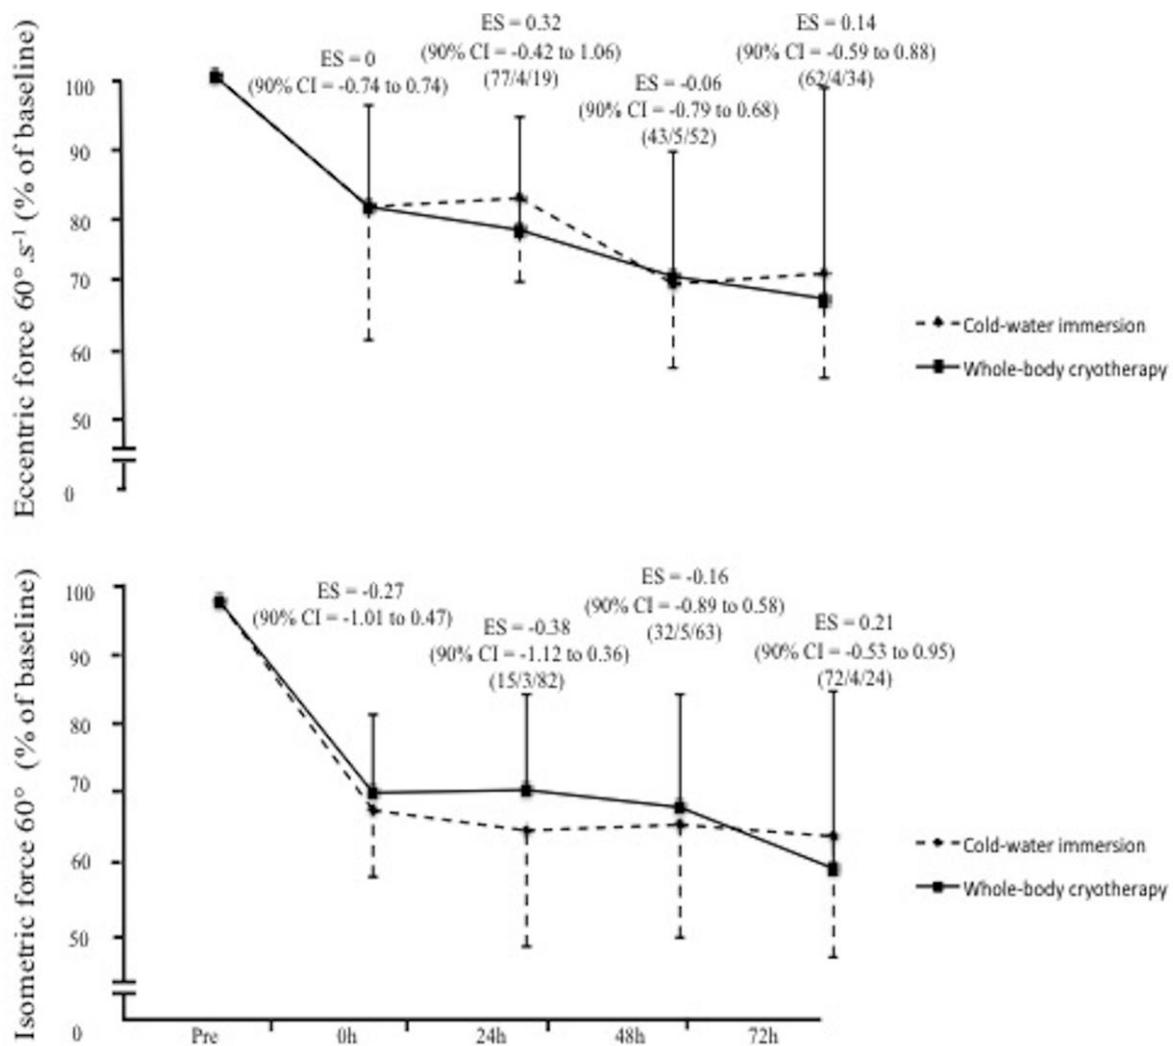

Figure 1: Time-evolution of eccentric force at 60°.s⁻¹ and isometric force at 60° in the cold-water and whole-body cryotherapy conditions at baseline (Pre), immediately (0h), 24h, 48h and 72h after the exercise induced muscle damage. ES = effect size between cold-water and whole-body cryotherapy. Probabilities to have an effect are presented as: (cold-water immersion/trivial/whole-body cryotherapy).

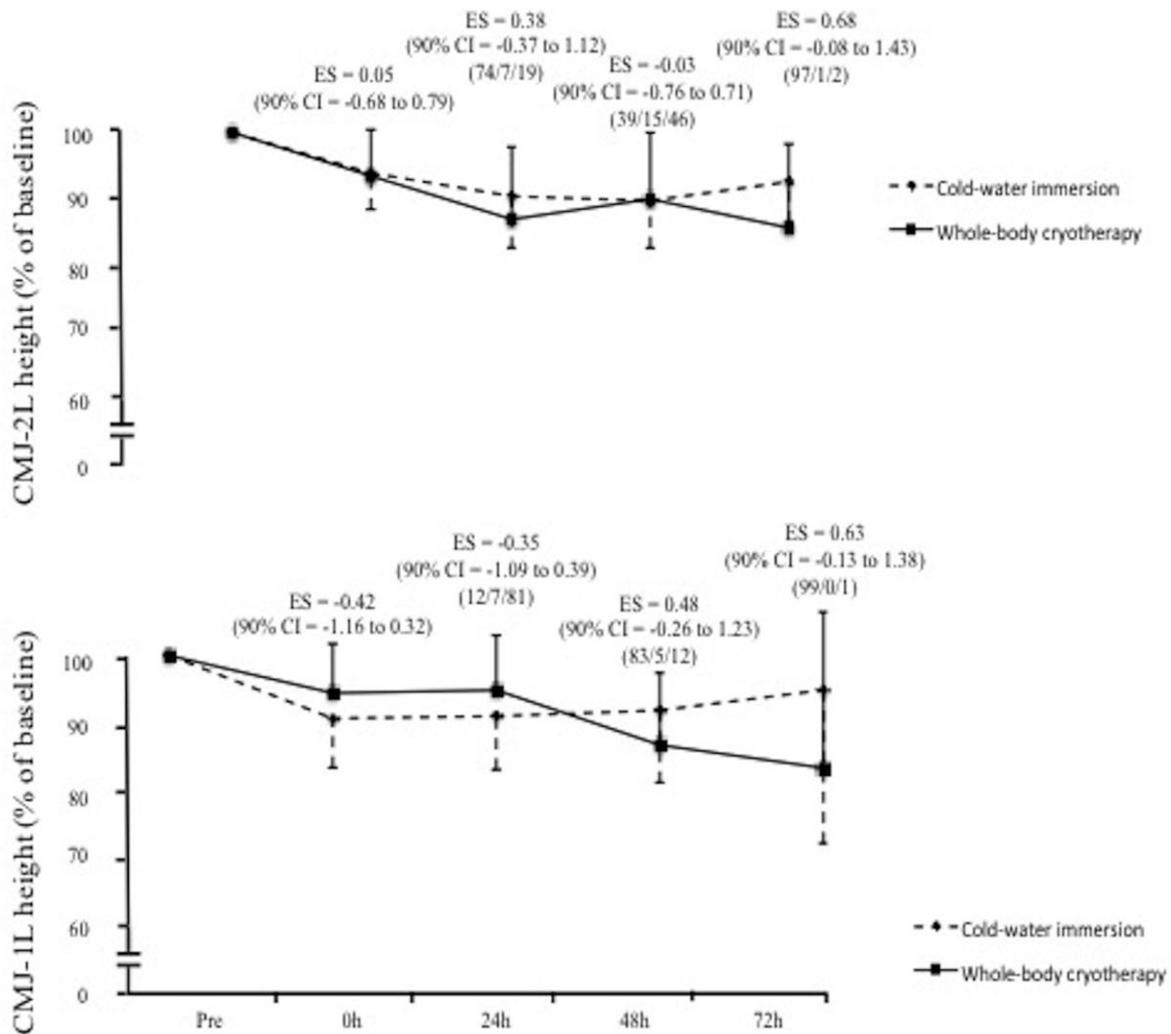

Figure 2: Time-evolution of single-leg (CMJ-1L) and two-legs countermovement jump (CMJ-2L) in the cold-water and whole-body cryotherapy conditions at baseline (Pre), immediately 0h), 24h, 48h and 72h after the exercise induced muscle damage. ES = effect size between cold-water and whole-body cryotherapy. Probabilities to have an effect are presented as: (cold-water immersion/trivial/whole-body cryotherapy).

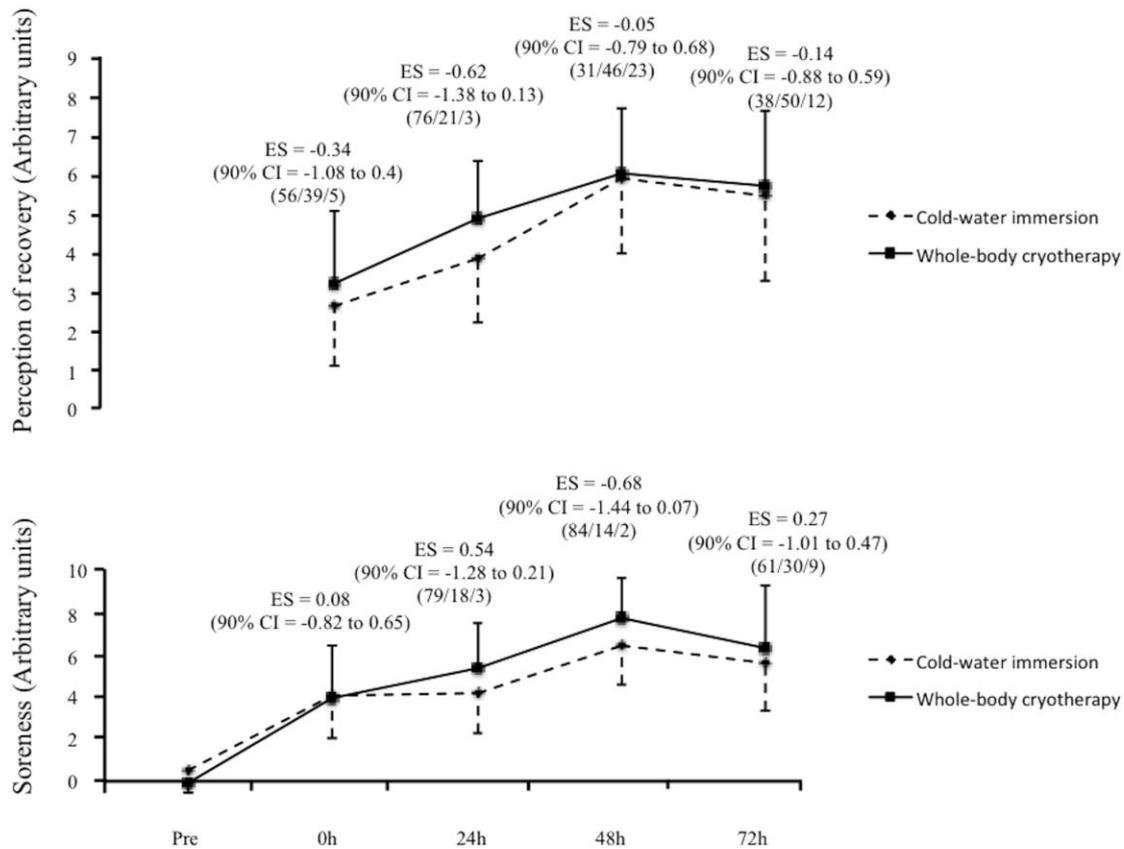

Figure 3: Time-evolution of muscle soreness and perception of recovery in the cold-water and whole-body cryotherapy conditions at baseline (Pre), immediately (0h), 24h, 48h and 72h after the exercise induced muscle damage. ES = effect size between cold-water and whole-body cryotherapy. Probabilities to have an effect are presented as: (cold-water immersion/trivial/whole-body cryotherapy).

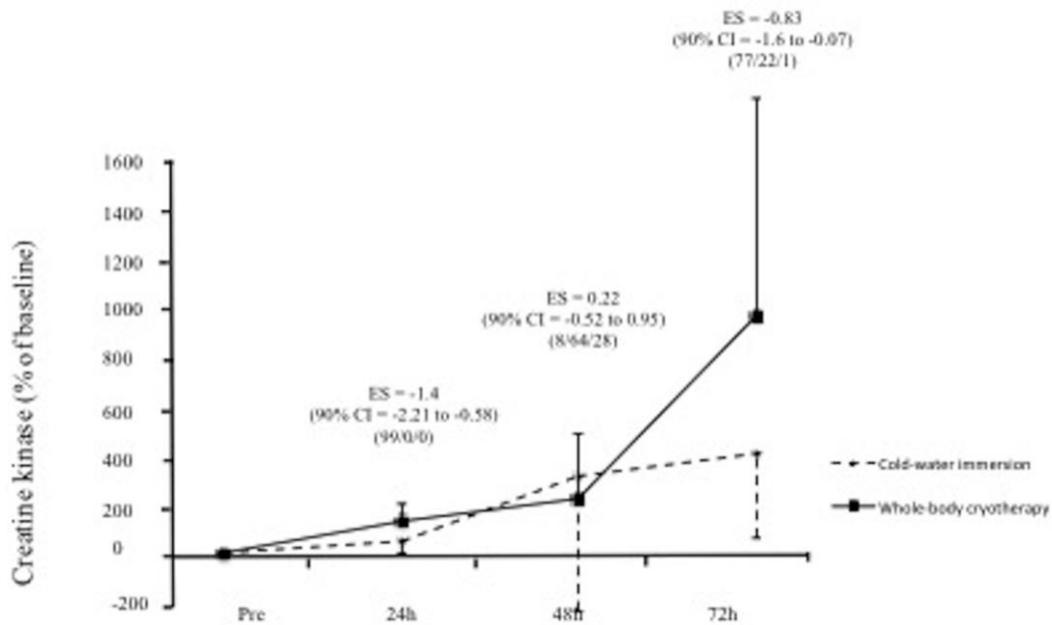

Figure 4: Time-evolution of creatine kinase concentrations in the cold-water and whole-body cryotherapy conditions at baseline (Pre), 24h, 48h and 72h after the exercise induced muscle damage. ES = effect size between cold-water and whole-body cryotherapy. Probabilities to have an effect are presented as: (cold-water immersion/trivial/whole-body cryotherapy).

Table 1: Reliability of outcomes measured during the experimental protocol.

	Trial 1	Trial 2	Effect Size (90% CI)	TE (90% CI)	ICC (90% CI)	CV
Eccentric Force 60°.s⁻¹ (N.m⁻¹)	194.7±29.1	200.5±44.3	0.15 (90% CI= -0.6 to 0.9)	16.76 (90% CI= 12 to 28.7)	0.85 (90% CI= 0.6 to 1)	12%
Isometric Force 60° (N)	144.2±26	144.8±28	0.02 (90% CI= -0.8 to 0.8)	4.05 (90% CI= 2.7 to 7.8)	0.98 (90% CI= 0.9 to 1)	3.9%
CMJ-1L (cm)	17.5±4.2	16.8±4.6	-0.16 (90% CI= -1.04 to 0.7)	0.85 (90% CI= 0.5 to 2.5)	0.97 (90% CI= 0.8 to 0.99)	9.4%

Trial 1 and trial 2 are respectively the first and second trial performed by the subjects after the familiarization for each outcome concerned.

Table 2: Time effect of each outcome in comparison with baseline value.

Outcome	Condition	0h	24h	48h	72h
Eccentric Force 60°.s⁻¹ (N.m⁻¹)	CWI	ES = -1.38 (90% CI = -2.2 to -0.6)	ES = -1.97 (90% CI = -2.9 to -1.1)	ES = -3.64 (90% CI = -4.8 to -2.5)	ES = -2.79 (90% CI = -3.8 to -1.9)
	WBC	ES = -1.84 (90% CI = -2.7 to -1)	ES = -1.91 (90% CI = -2.8 to -1)	ES = -2.23 (90% CI = -3.2 to -1.3)	ES = -1.51 (90% CI = -2.3 to -0.7)
Isometric force 60° (N)	CWI	ES = -4.29 (90% CI = -5.6 to -3)	ES = -2.71 (90% CI = -3.7 to -1.7)	ES = -2.8 (90% CI = -3.8 to -1.8)	ES = -2.79 (90% CI = -3.8 to -1.8)
	WBC	ES = -3.57 (90% CI = -4.7 to -2.4)	ES = -2.82 (90% CI = -3.8 to -1.8)	ES = -2.58 (90% CI = -3.6 to -1.6)	ES = -2.15 (90% CI = -3.1 to -1.2)

	WBC	ES = -1.03 (90% CI = -1.8 to -0.3)	ES = -0.81 (90% CI = -1.6 to -0)	ES = -1.7 (90% CI = -2.6 to -0.9)	ES = -1.02 (90% CI = -1.8 to -0.3)
[CK] (U.L⁻¹)	CWI	N/A	ES = 1.33 (90% CI = 0.5 to 2.1)	ES = 0.8 (90% CI = 0.04 to 1.6)	ES = 1.67 (90% CI = 0.8 to 2.5)
	WBC	N/A	ES = 2.68 (90% CI = 1.7 to 3.7)	ES = 1.17 (90% CI = 0.4 to 2)	ES = 1.53 (90% CI = 0.7 to 2.4)
Soreness (AU)	CWI	ES = 2.15 (90% CI = 1.2 to 3.1)	ES = 2.35 (90% CI = 1.4 to 3.3)	ES = 3.86 (90% CI = 2.7 to 5.1)	ES = 2.88 (90% CI = 1.9 to 3.9)
	WBC	ES = 2.18 (90% CI = 1.3 to 3.1)	ES = 3.7 (90% CI = 2.5 to 4.9)	ES = 5.88 (90% CI = 4.2 to 7.5)	ES = 3.17 (90% CI = 2.1 to 4.3)
Perception of recovery (AU)	CWI	N/A	ES = 0.79 (90% CI = 0 to 1.6)	ES = 1.88 (90% CI = 1 to 2.8)	ES = 1.51 (90% CI = 0.7 to 2.3)
	WBC	N/A	ES = 0.99 (90% CI = 0.2 to 1.8)	ES = 1.61 (90% CI = 0.8 to 2.5)	ES = 1.33 (90% CI = 0.5 to 2.1)

CWI = cold-water immersion. WBC = whole-body cryotherapy. [CK] = creatine kinase concentrations. AU = arbitrary units. This table presents a comparison of each time point mean value with baseline values in each condition. The information given is the time effect of the exercise. The effect sizes (ES) and confidence intervals (CI) represent the difference between a given time point and the baseline value for the considered outcome.
